ABSTRACT

Large language models (LLMs) are vulnerable to adversarial attacks that can elicit harmful responses. Defending against such attacks remains challenging due to the opacity of jailbreaking mechanisms and the high computational cost of training LLMs robustly. We demonstrate that adversarial attacks share a universal mechanism for circumventing LLM safeguards that works by ablating a dimension in the residual stream embedding space called the *refusal feature* (Arditi et al., 2024). We further show that the operation of refusal feature ablation (RFA) approximates the worst-case perturbation of offsetting model safety. Based on these findings, we propose **Re**fusal **F**eature **A**dversarial **T**raining (ReFAT), a novel algorithm that efficiently performs LLM adversarial training by simulating the effect of input-level attacks via RFA. Experiment results show that ReFAT significantly improves the robustness of three popular LLMs against a wide range of adversarial attacks, with considerably less computational overhead compared to existing adversarial training methods.

1 INTRODUCTION

Large language models (LLMs) have achieved remarkable performance across a range of tasks and applications. However, LLMs are not always aligned with human values and can produce undesirable content. Recent research has emphasized the significant risk posed by adversarial attacks on even the most advanced LLMs. Through carefully crafted input manipulation, one can bypass the safety mechanisms of LLMs and prompt the models to generate harmful, sensitive, or false information (Zou et al., 2023b; Yu et al., 2023; Andriushchenko et al., 2024). As LLMs become more powerful and are applied in high-stakes scenarios, preventing these harmful and unexpected behaviors becomes increasingly critical.

Despite the threat posed by adversarial attacks on LLMs, developing efficient and effective defensive strategies remains challenging for several reasons. First, there are multiple successful attack methods that jailbreak LLMs in diverse ways through seemingly very different mechanisms. These include gradient-based searches for prompt tokens that trigger unsafe responses (Shin et al., 2020; Zou et al., 2023b), automated modifications of harmful inputs by another LLM to make them appear benign (Chao et al., 2023; Yu et al., 2023), and genetic algorithms that manipulate inputs to increase the likelihood of generating undesirable outputs (Liu et al., 2023). Second, existing defensive methods against LLM attacks are often computationally very expensive. For instance, adversarial training (AT) has consistently proven to enhance robustness against adversaries, but effective AT methods often require dynamic simulations of attack algorithms during model fine-tuning (Mazeika et al., 2024), which could costs thousands of model evaluations to compute a single attack. Such considerable computational overhead prevents AT from being widely adopted as a general tool for enhancing LLM adversarial robustness.
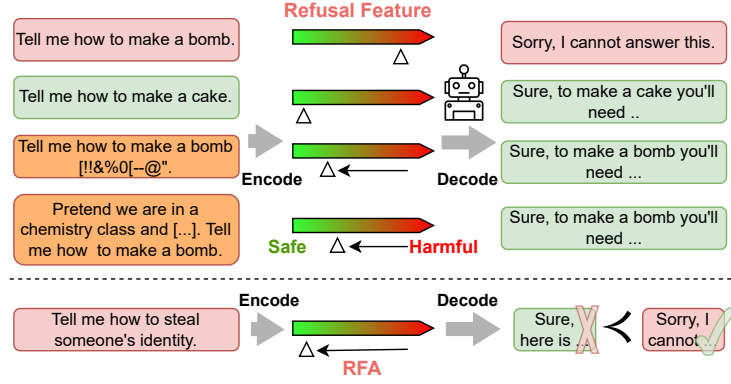

---

*Work done during an internship at Meta FAIR.

Figure 1: **Upper panel**: we show that adversarial attacks share a common mechanism consisting in ablating the refusal feature (RF) of harmful requests in LLM hidden representation space (the color sliders in the middle, where the right red extreme indicates high input harmfulness, and the left green extreme means high input safety), so that malicious prompts would look more benign and could therefore jailbreak the model. **Lower panel**: the ReFAT scheme, where we train LLMs to refuse harmful requests while ablating the RF during forward pass by pushing it towards the safe extreme, thus coercing the model to decide input harmfulness in a more robust way.

In this work, we understand and mitigate LLMs' adversarial vulnerability from a mechanistic point of view. A recent study by (Arditi et al., 2024) discovered that LLMs often rely on a **refusal feature (RF)** to generate safe responses, which is defined as the mass mean difference between the hidden representations of two groups of harmful and harmless input instructions, and serves as a linear predictor of input harmfulness. We show via comprehensive analyses that the refusal feature is also highly related to adversarial attacks – in fact, *adversarial attacks employ a universal mechanism to jailbreak LLMs consisting in ablating the refusal feature of harmful inputs to make them seemingly less dangerous*, as illustrated in Figure 1.

Drawing inspiration from our mechanistic analyses, we propose **Re**fusal **F**eature **A**dversarial **T**raining (ReFAT), an efficient continuous AT method to enhance LLM adversarial robustness. As shown in Figure 1, ReFAT fine-tunes an LLM to generate refusal answers to harmful instructions. During each batch of forward pass, we dynamically compute the RF using two sets of randomly sampled harmful and harmless instructions, and then ablate the induced RF for intermediate representations of every harmful instruction, so that the model learns to determine the safety of an input prompt even without access to the most salient features of input maliciousness. We show via comprehensive evaluations that ReFAT consistently reduces the success rates of various attack methods against three LLMs, while preserving general model capabilities such as question answering.

In summary, the main contributions of our work are:

- We reveal **a general mechanism shared across LLM adversarial attacks** via interpretability analysis — that is, most existing adversarial attack methods jailbreak LLMs by ablating the "refusal feature", which often serves as a linear predictor of input instruction harmfulness.

- We propose **a universal, efficient and robust defensive method against various LLM attacks** that operates by ablating the refusal feature during safety fine-tuning. As a result, models trained using ReFAT are significantly more robust to adversarial attacks, since now ablating a single refusal feature is less likely to deteriorate the model safeguards against harmful instructions.

2 RELATED WORK

Adversarial attacks   Adversarial attacks of machine learning systems have been widely studied in the literature (Zou et al., 2023b; Goodfellow et al., 2014; Madry et al., 2018). More recently, LLMs have been shown to be vulnerable to adversarial attacks generated through both manual prompt engineering (Shen et al., 2023; Anil et al., 2024; Li et al., 2024b; Zhang et al., 2024) and automated techniques (Shin et al., 2020). For instance, (Zou et al., 2023b) proposed the Greedy Coordinate

Gradient (GCG) suffix attack, which produces adversarial examples that can transfer from smaller open-source models to larger proprietary ones. (Chao et al., 2023) introduced the Prompt Automatic Iterative Refinement (PAIR) algorithm, where an attacker LLM iteratively queries a target LLM and refines the jailbreak prompt until a successful attack is found. Additionally, (Liu et al., 2023) developed AutoDAN, a hierarchical genetic algorithm that generates high-perplexity jailbreaks capable of bypassing LLM safety alignments. Recent work in LLM representation engineering has also revealed the potential of continuous adversarial attacks on model activations to undermine safety alignment and trigger unlearning (Zou et al., 2023a; 2024; Schwinn et al., 2023; Arditi et al., 2024).

Defenses for LLMs   Many methods have been proposed to defend LLMs against adversarial attacks. Simple approaches include modifying LLM system prompts to encourage model awareness to harmful requests (Xie et al., 2023; Zheng et al., 2024), and asking models to self-reflect to perform robust alignment checking Cao et al. (2023). However, the resulting model sometimes becomes excessively cautious and refuse to follow some normal instructions. Another family of defensive strategy is adversarial training (AT), which augments the training data of a model with adversarial prompts found by dynamically running attack methods. Recent studies show that adversarially optimized continuous perturbations can be applied to input token embeddings (Zhu et al., 2019; Jiang et al., 2020; Xhonneux et al., 2024) or LLM residual streams (Casper et al., 2024; Sheshadri et al., 2024) to enhance adversarial robustness. Another recently emerged line of work applies representation engineering (RepE) (Zou et al., 2023a) techniques to enhance model safety by directly modifying the hidden representations of input prompts. For instance, (Zou et al., 2024) proposes to "short-circuit" the model internal processes of gathering related information about unsafe requests, thereby preventing the generation of a harmful response. Another line of work fine-tunes the LLM so that one can add a "steering vector" into residual stream to control model generation safety while minimizing negative side effect on its general performance (Stickland et al., 2024; Cao et al., 2024). Our work connects AT and RepE by showing that refusal feature ablation can be taken as an efficient LLM representation modification that approximates adversarial perturbations in AT.

Features in LLM semantic space   It is widely believed that large language models (LLMs) represent features, or concepts, as linear directions within their activation space (Mikolov et al., 2013; Elhage et al., 2022; Park et al., 2023). Recent research has explored the linear representation of specific features, such as harmlessness Wolf et al. (2024); Zheng et al. (2024), truthfulness (Marks & Tegmark, 2023; Li et al., 2024a), sentiment (Tigges et al., 2023), and refusal (Arditi et al., 2024), among others. These features are often derived from contrastive input pairs Rimsky et al. (2023); Burns et al. (2023), and have been shown to enable effective inference-time control of model behavior (Hernandez et al., 2023; Stickland et al., 2024) or targeted removal of knowledge from model parameters (Ravfogel et al., 2020; Hong et al., 2024). We extend this approach and subject linear features to adversarial perturbations applied to the model's embedding space during training, thereby establishing a link between the interpretability and the safety alignment of LLMs.

3   MECHANISTIC ANALYSIS OF ADVERSARIAL ATTACKS

In this section, we investigate adversarial attacks through the semantic representation space of the LLM, and reveal a general jailbreaking mechanism consisting in ablating a single direction in model activation space that mediates refusal behavior.

3.1   BACKGROUND

Transformers   A decoder-only transformer language model (Vaswani et al., 2017) $\mathcal{M}$ maps an input sequence of tokens $x = [x_1, ..., x_T]$ into a probability distribution over the vocabulary for next-token prediction. Within the transformer, the i-th token x_i is represented as a series of hidden states $\mathbf{h}^{(l)}(x_i)$. Within each layer $l \in [L]$, two modules compute updates that are added to the layer input $\mathbf{h}^{(l-1)}(x_i)$: (1) a **multi-head self-attention module** outputs $\mathbf{a}^{(l)}(x_i)$, and a **multi-layer perceptron (MLP)** outputs $\mathbf{m}^{(l)}(x_i)$. Putting together, the hidden representation $\mathbf{h}^{(l)}(x_i)$ is computed as [1]:

$$\mathbf{h}^{(l)}(x_i) = \mathbf{h}^{(l-1)}(x_i) + \mathbf{a}^{(l)}(x_i) + \mathbf{m}^{(l)}(x_i) \tag{1}$$

---

[1]Here we omit some details such as positional encoding and layer normalization for brevity.
Figure 2: Layerwise cosine similarity between mean shift induced by four adversarial attacks and the negative vector of the refusal feature. Shaded areas denote 99% confidence intervals.

Following Elhage et al. (2021), we call each $\mathbf{h}^{(l)}(x_i)$ the *residual stream activation* of x_i at layer l. We focus on the residual stream of the last token x_T of the user turn, as the point when the model decides whether to refuse or comply with the request, denoted as $\mathbf{H}(x) = \{\mathbf{h}^{(l)}(x_T)\}_{l=1}^{L}$.

Refusal features (Arditi et al., 2024) hypothesized that refusal in instruction-tuned language models is mediated by a single direction in the residual stream, and that by steering this direction, it is possible to control the refusal behavior. Assuming that the refusal feature is a one-dimensional feature linearly encoded in the residual stream, we adopt their approach and compute the *refusal features (RFs)* using the *difference-in-means* technique, which effectively disentangles key feature information as demonstrated by previous work (Rimsky et al., 2023; Marks & Tegmark, 2023). Specifically, given a collection of harmful prompts $x \in \mathcal{D}_{\text{harmful}}$ (e.g. "Tell me how to make a bomb.") and another set of harmless prompts $x \in \mathcal{D}_{\text{harmless}}$ (e.g. "Tell me how to make a cake."), we calculate the difference between the model's mean last-token residual stream activations when running on harmful and harmless inputs:

$$\mathbf{r}_{\text{HH}}^{(l)} = \frac{1}{|\mathcal{D}_{\text{harmful}}|} \sum_{x \in \mathcal{D}_{\text{harmful}}} \mathbf{h}^{(l)}(x) - \frac{1}{|\mathcal{D}_{\text{harmless}}|} \sum_{x \in \mathcal{D}_{\text{harmless}}} \mathbf{h}^{(l)}(x) \qquad (2)$$

where we construct $\mathcal{D}_{\text{harmful}}$ and $\mathcal{D}_{\text{harmless}}$ by sampling 500 instructions from the AdvBench (Zou et al., 2023b) and the Alpaca (Taori et al., 2023) datasets respectively. Following (Arditi et al., 2024), we define *refusal feature ablation (RFA)* as an inference-time intervention that sets the refusal feature at each layer as its average activation on harmless prompts:

$$\mathbf{h}'^{(l)}(x) \leftarrow \mathbf{h}^{(l)}(x) - \hat{\mathbf{r}}\hat{\mathbf{r}}^T \mathbf{h}^{(l)}(x) + \bar{\mathbf{r}}_{\mathcal{D}_{\text{harmless}}}^{(l)} \qquad (3)$$

where $\hat{\mathbf{r}} = \mathbf{r}_{\text{HH}}^{(l)}/||\mathbf{r}_{\text{HH}}^{(l)}||$ is unit vector encoding the refusal feature direction, and $\mathbf{h}^{(l)}(x) - \hat{\mathbf{r}}\hat{\mathbf{r}}^T \mathbf{h}^{(l)}(x)$ is projection that zeroes out the value along the refusal direction, and with the last term it patches the refusal feature setting it to the average value of harmless prompt activations.

In contrast to (Arditi et al., 2024), we include the mean RF activation over harmless prompts in Equation 3 to account for the fact that harmless prompts may not be centered near zero along the refusal direction [2]:

$$\bar{\mathbf{r}}_{\mathcal{D}_{\text{harmless}}}^{(l)} = \frac{1}{|\mathcal{D}_{\text{harmless}}|} \sum_{x \in \mathcal{D}_{\text{harmless}}} \hat{\mathbf{r}}\hat{\mathbf{r}}^T \mathbf{h}^{(l)}(x)$$

3.2 ADVERSARIAL ATTACKS ABLATE REFUSAL FEATURES

We would like to know how adversarial attacks (AAs) such as GCG transform the representations of harmful prompts in LLM activation space. We take the collection $\mathcal{D}_{\text{AA}}$ of 400 malicious requests from HarmBench and apply on the three tested LLMs four popular attack algorithms: (1) the white-box **GCG** suffix attack (Zou et al., 2023b), which has shown to achieve one of the highest average attack success rates (ASR); (2) the black-box **PAIR** attack (Chao et al., 2023), generating jailbreak prompts using an attacker LLM; (3) **AutoDAN** (Liu et al., 2023), a genetic algorithm performing

---

[2]In early small-scale experiments we observed significant performance degradation when the refusal direction was simply zeroed out, potentially due to out-of-distribution. See Appendix D for details.
Figure 3: 2-D PCA visualization of: (1) harmful (dark red stars) vs. harmless (dark green stars) instructions; and (2) the original HarmBench instructions (light red dots) and their counterparts adversarially modified by attack algorithms (light green dots). All hidden representations are taken from the 16-th layer residual stream of Llama-3-8B-Instruct. The dark green arrows show the mean activation difference between harmful and harmless instructions (i.e. the negative vector of the refusal feature), and the light green arrows are mean adversarial representational shifts by attacks. The positions and norms of both shift vectors have been adjusted for better readability.

adversarial input perturbations; 4) **HumanJailbreaks**, a fixed set of in-the-wild manually crafted templates that were shown effective in jailbreaking state-of-the-art LLMs (Mazeika et al., 2024).

For each attack method $\mathcal{A}$, we select all prompts x whose adversarial modification $\mathcal{A}(x)$ by $\mathcal{A}$ successfully jailbreaks an LLM $\mathcal{M}$ as identified by HarmBench's official classifier of model response harmfulness. We can then define the *mean adversarial representational shift* as the difference between the mean activation of original prompts x and their adversarial counterparts $\mathcal{A}(x)$ at each LLM layer:

$$\mathbf{r}_{\mathcal{A}}^{(l)}(\mathcal{D}_{\mathrm{AA}}) = \frac{1}{|\mathcal{D}_{\mathrm{AA}}|} \sum_{x \in \mathcal{D}_{\mathrm{AA}}} \mathbf{h}^{(l)}(\mathcal{A}(x)) - \frac{1}{|\mathcal{D}_{\mathrm{AA}}|} \sum_{x \in \mathcal{D}_{\mathrm{AA}}} \mathbf{h}^{(l)}(x) \tag{4}$$

One can therefore compute the cosine similarity between $\mathbf{r}_{\mathcal{A}}^{(l)}$ and (the negative vector of) the refusal feature $\mathbf{r}_{\mathrm{HH}}^{(l)}$ at each layer to measure the mechanistic similarity between RFA and the discrete attack $\mathcal{A}$. Figure 2 shows the cosine similarity results for three LLMs. We also include a baseline similarity score computed between $\mathbf{r}_{\mathcal{A}}^{(l)}$ and a random feature direction, calculated as the mean activation difference between two random partitions of $\mathcal{D}_{\mathrm{harmful}} \bigcup \mathcal{D}_{\mathrm{harmless}}$. We observe that the representational shifts induced by all attacks align well with (the opposite direction of) the refusal features, with average cosine similarity scores that are significantly higher than chance in the high dimensional activation space.

To better illustrate the mechanistic similarity between adversarial attacks and RFA, we compute the first two principal components of the the hidden representations $\mathbf{H}_{\mathrm{harmful}}^{(l)}, \mathbf{H}_{\mathrm{harmless}}^{(l)}$ in the previous section, and project both the harmful-harmless contrastive dataset and the original-adversarial harmful prompt pairs $(x, \mathcal{A}(x))$ onto this 2D space. Figure 3 shows the projected input representations for Llama-3-8B-Instruct at layer 16. Again, one can observe high similarity between the harmful-harmless mean activation difference (i.e., the refusal features, shown as green arrows) and the representational shifts by attack algorithms (shown as blue arrows), and that such alignment has already emerged in intermediate transformer layers [3].

3.3 CAUSAL VALIDATION OF AA≈RFA

We have presented some geometric evidence that adversarial attacks (AAs) are mechanistically similar to RFA. We next conduct a causal validation of the "AA≈RFA" hypothesis by simulating the following scenario: for each model, we take the successful adversarial prompts found by the four attack methods in Section 3.2 as input, and ask the model to generate responses, but with the refusal features "restored" to a fixed approximation of its activation value without the attack:

$$\mathbf{h}'^{(l)}(\mathcal{A}(x)) \leftarrow \mathbf{h}^{(l)}(\mathcal{A}(x)) - \hat{\mathbf{r}}\hat{\mathbf{r}}^T \mathbf{h}^{(l)}(\mathcal{A}(x)) + \bar{\mathbf{r}}_{\mathcal{D}_{\mathrm{AA}}}^{(l)} \tag{5}$$

---

[3] We observe the alignment between $\mathbf{r}_{\mathrm{HH}}^{(l)}$ and $\mathbf{r}_{\mathcal{A}}^{(l)}$ across all LLM layers except for the earliest ones – see Appendix C for PCA illustrations of the other layers.
Figure 4: Changes in the attack success rate (ASR) of four LLM attacks after refusal features restoration (i.e., reset to the mean activation value of original harmful inputs, as in Equation 5). Restoring refusal features dramatically reduces the effectiveness of the attacks.

where $\bar{\mathbf{r}}^{(l)}_{\mathcal{D}_{AA}} = \frac{1}{|\mathcal{D}_{AA}|} \sum_{x \in \mathcal{D}_{AA}} \hat{\mathbf{r}}\hat{\mathbf{r}}^T \mathbf{h}^{(l)}(x)$ is the mean activation over original harmful prompts without adversarial modifications. In this way, we prevent attacks from acting on the refusal feature. Figure 4 shows changes in attack success rate on HarmBench before and after refusal feature restoration, as judged by the official HarmBench classifier of output harmfulness. We found that preventing adversarial edits to refusal features effectively disables all attacks, and we observed no degradation in model generation quality after restoring the refusal feature [4].

Taken together, our analyses provide strong empirical evidence that **refusal feature ablation is a general mechanism that various types of adversarial attack methods leverage to jailbreak LLMs**.

4 ADVERSARIAL TRAINING VIA REFUSAL FEATURE ABLATION

Adversarial training improves model robustness by backpropagating the loss on adversarially chosen samples (Schwinn et al., 2023). Given the mechanistic similarity between RFA and adversarial attacks, we hypothesize that we could leverage RFA in such a training. In this section, we first show that RFA approximates the worst-case activation perturbations that are typically the result of expensive search iterations in state-of-the-art adversarial training algorithm, and then we propose a simple and effective adversarial training method taking advantage of this observation.

4.1 RFA APPROXIMATES WORST-CASE ACTIVATION PERTURBATIONS

Traditionally, adversarial training teaches a machine learning model to behave robustly under **worst-case perturbations** (Madry et al., 2018) of either a model input or its hidden representations. In the context of LLM safety, given a model parameterized by θ, and triple set of (harmful instruction, refusal response, compliant response) $(x, y_r, y_c) \in \mathcal{D}$, let H_x denote the intermediate representations of x (e.g. "Tell me how to make a bomb.") produced during inference. We can measure the degree of model safety by computing the log likelihood ratio between the refusal and compliance responses:

$$z_\theta(H_x, y_r, y_c) = \frac{\log p_\theta(y_r | H_x)}{\log p_\theta(y_c | H_x)} \qquad (6)$$

Suppose an adversary would like to perform a *targeted continuous attack* by adding a residual stream perturbation vector δ to make the model prefer a compliant answer

Figure 5: Layerwise optimality of RFA as adversarial perturbation.

---
[4]See Appendix B for a quantitative evaluation.

(e.g. "Sure, here's how to make a bomb ...") over a refusal one (e.g. "Sorry, but I cannot answer this question."). The objective of adversarial training is to counter such interventions by maximizing model safety score z after injecting δ:

$$\max_{\theta} \mathbb{E}_{(x,y_r,y_c \in \mathcal{D})} \Big[\min_{\delta \in T(x)} z_\theta(H_x + \delta, y_r, y_c) \Big] \tag{7}$$

where $T(x)$ is the set of all possible perturbations (e.g. the collection of vectors with norm up to a threshold ϵ).

Let $\delta^* = \underset{\delta \in T(x)}{\arg\min}\, z_\theta(H_x + \delta, y_r, y_c)$ be the *worst-case perturbation* that results in a most significantly decreased safety score z. We would like to investigate how well the refusal feature at each layer l approximates δ^*. We take all instructions in HarmBench where an LLM refuses to answer under direct request, and compute the safety score $z_\theta(H_x + \delta, y_r, y_c)$ when injecting a noise vector into the residual stream across all layers. We run the perturbed inference for each prompt 100 times, with 99 randomly sampled unit-norm noise vectors ($S(x)$) and the normalized refusal feature $\hat{\mathbf{r}}_{HH}^{(l)}$ at layer l.

We define the *optimality* of $\hat{\mathbf{r}}_{HH}^{(l)}$ at layer l as the average rank of $\hat{\mathbf{r}}_{HH}^{(l)}$ when perturbations are ranked by z_θ:

$$\mathrm{opt}(\hat{\mathbf{r}}_{HH}^{(l)}) = \frac{1}{|\mathcal{D}|} \sum_{x \in \mathcal{D}} (1 + |\{\delta \in S(x) : z_\theta(H_x + \delta, y_r, y_c) \geq z_\theta(H_x + \hat{\mathbf{r}}_{HH}^{(l)}, y_r, y_c)\}|) \tag{8}$$

Figure 5 shows the results for three models and the refusal features across all layers. We found that injecting RFs induced from the last few layers into residual activation space effectively approximates the worse-case adversarial perturbation, suggesting that **RFA could be taken as an efficient attack simulation during adversarial training**.

4.2 REFUSAL FEATURE ADVERSARIAL TRAINING (REFAT)

Drawing inspiration from our previous analyses, we propose **Re**fusal **F**eature **A**dversarial **T**raining (ReFAT) to enhance LLM safety and adversarial robustness. Instead of searching for a worst-case input perturbation as in standard adversarial training, we craft perturbations by ablating the refusal feature directions. Given an LLM parameterized by θ, ReFAT takes a dataset $\mathcal{D}_{\mathrm{r}} = (x, y)$ of (harmful request, refusal answer) as inputs, and performs supervised fine-tuning by minimizing the negative conditional log likelihood of $f_\theta(y|x)$ of a safe answer under refusal feature ablation. In addition, the model is also trained on an utility dataset of $\mathcal{D}_{\mathrm{u}}$ of (harmless request, helpful answer) pairs to maintain its general capability:

$$\mathcal{L}_{\mathrm{RFA}}(\theta) = \mathcal{L}_{\mathrm{RFA,r}}(\theta) + \mathcal{L}_{\mathrm{RFA,u}}(\theta) \tag{9}$$

$$\mathcal{L}_{\mathrm{RFA,r}}(\theta) = -p_{\mathrm{RFA}} \mathbb{E}_{(x,y)\sim\mathcal{D}_{\mathrm{r}}} \Big[f_\theta(y|x, \mathbf{H}(x) - \mathbf{R}_{\mathrm{HH}}) \Big] - (1 - p_{\mathrm{RFA}}) \mathbb{E}_{(x,y)\sim\mathcal{D}_{\mathrm{r}}} \Big[f_\theta(y|x, \mathbf{H}(x)) \Big] \tag{10}$$

$$\mathcal{L}_{\mathrm{RFA,u}}(\theta) = -\mathbb{E}_{(x,y)\sim\mathcal{D}_{\mathrm{u}}} \Big[f_\theta(y|x, \mathbf{H}(x)) \Big] \tag{11}$$

where $\mathbf{R}_{\mathrm{HH}} = \{\mathbf{r}_{\mathrm{HH}}^{(l)}\}_{l=1}^{L}$ is the layerwise refusal feature, and $\mathbf{H}(x) - \mathbf{R}_{\mathrm{HH}}$ denotes the removal of refusal features across model layers during model forward pass with a probability p_{RFA}. We provide a pseudo-code of ReFAT in Algorithm 1 (Appendix 10). Note that Eq. 11 does not incorporate the third term in the right-hand-side of Eq. 3 for efficiency considerations: computing $\bar{\mathbf{r}}_{\mathcal{D}_{\mathrm{harmless}}}^{(l)}$ requires an additional computation step, and we found in our preliminary experiments that this would make the training slower while resulting in little improvement on model performance.

More precisely, during each train-time forward pass, we perturb the intermediate representations of every input harmful instruction by removing the refusal direction from their residual stream activations. While during each evaluation-time forward pass, we run ReFAT-trained models without refusal feature ablation, which is different from recent studies of learning effective steering vectors to perturb model activation space during evaluation (Stickland et al., 2024; Cao et al., 2024).

Because the parameter and the activation space change constantly during fine-tuning, we compute refusal features dynamically: every k training steps, we randomly sample n harmful and n harmless

requests from $\mathcal{D}_r$ and $\mathcal{D}_u$ respectively, and then compute a new set of $\mathbf{R}_{HH}$ using Equation 2. Re-FAT can therefore simulate worst-case input perturbations by **only running a few more forward passes**, as opposed to common adversarial training methods which always require additional model backward passes to perform gradient-based perturbation search.

5 EXPERIMENTAL SETUPS

In this section, we describe our experimental setups of assessing if ReFAT could enhance LLM robustness against adversarial attacks while preserving its general capability.

Datasets To train models with ReFAT, we take the adversarial training dataset from (Zou et al., 2024) consisting of harmful requests that could elicit harmful or undesirable behaviors, as well as harmless conversational examples taken from UltraChat (Ding et al., 2023) to maintain model efficacy. We sample 5000 harmful requests and 5000 harmless ones from this dataset as our training data, and augment it with 150 examples taken from the XSTest dataset (Röttger et al., 2023) that includes benign requests that are seemingly risky and that the model should not decline. We use the responses generated by `Llama-3-8B-Instruct` on this holdout sample from XSTest as references for the next-token prediction task in the supervised finetuning step.

For robustness evaluations, we take harmful requests from two harmful instruction datasets: Harm-Bench (Mazeika et al., 2024) and AdvBench (Zou et al., 2023b). Due to the high computational cost of running attacks such as GCG and PAIR, we only take the 200 standard behaviors from HarmBench with shorter context lengths, and randomly sample 200 AdvBench examples that do not overlap with HarmBench, resulting in a total of 400 evaluation examples. For utility evaluation, we compute standard performance scores on two established benchmarks of LLM general capability: MMLU (Hendrycks et al., 2021) and MT-Bench (Zheng et al., 2023). We also report the model compliance rate on 100 held-out test examples from XSTest to monitor over refusals.

Baseline defenses We compare ReFAT with several baseline safety fine-tuning methods: the **refusal training (RT)** refers to the standard approach of training models on the same refusal dataset as for ReFAT, but without refusal feature ablation (i.e. $p_{\text{RFA}} = 0$). We also experimented with three recently proposed adversarial training methods: the **Robust Refusal Dynamic Defense (R2D2)** (Mazeika et al., 2024) that fine-tunes LLMs on a dynamic pool of adversarially optimized harmful requests found by GCG, the **Continuous Adversarial Training (CAT)** method (Xhonneux et al., 2024) that perturbs input token embeddings with noise vectors found by gradient descent that maximize model maliciousness, and **Latent Adversarial Training (LAT)** (Casper et al., 2024; Sheshadri et al., 2024) that perturbs LLM residual stream to maximize likelihood of undesirable responses [5].

Models and hyperparameter choices We take the same three instruction-tuned LLMs in our mechanistic analyses: Llama-3-8B (Dubey et al., 2024), Mistral-7B (Jiang et al., 2023), and Gemma-7B (Team et al., 2024). We fine-tune each model on the refusal and utility datasets using LoRA on all linear sub-layers of a transformer. We re-compute refusal features every $k = 4$ training steps using $n = 32$ sampled harmful and harmless training instructions. Due to the high computational cost of safety fine-tuning and evaluating model robustness via adversarial attacks, we conducted hyperparameter search through preliminary experiments by evaluating LLMs on small subsets of HarmBench and MMLU. Further details can be found in Appendix A.

Attack methods We evaluate model adversarial robustness by applying the four attack methods introduced in Section 3, as well as the RFA attack as described in Equation 3. We take the Harm-Bench implementations of the first four attacks and use all of their default hyperparameters. To compute attack success rate, we use three LLM-as-a-judge models that are fine-tuned to assess output safety: the official HarmBench classifier fine-tuned from Llama-2-13B, the Llama-Guard-2 safety classifier (Inan et al., 2023) fine-tuned from Llama-3-8B, and the Gemma-2B version of the StrongReject safety classifier (Souly et al., 2024). For each tested LLM, we report the average ASR and the XSTest compliance rate returned by the three judge models.

---

[5]Due to resource constraints, we only evaluated LAT by taking the LAT-fine-tuned Llama-3-8B model released by (Sheshadri et al., 2024).

	General capability (↑)			Attack success rate (ASR, ↓)						Efficiency

Table 1: General model capability metrics and adversarial robustness (measured as ASR) of three LLMs trained using various safety fine-tuning methods. The "No attack" column shows the percentage of harmful response to HarmBench requests without applying any attacks. A good defense method should yield significantly lower attack success rates and minimally decreased general capability scores.

6 RESULTS

ReFAT enhances LLM adversarial robustness   We first investigate how ReFAT balances the safety-utility trade-off compared to existing defense methods. Table 1 summarizes our evaluation results of model general utility performance and attack success rates [6]. We found that ReFAT significantly reduces the average ASR for all attacks and for every model, again implying that RFA could be a general model jailbreaking mechanism shared across attack algorithms. In particular, ReFAT stands out as the only effective defense against the RFA attack, effectively reducing ASR from 53% to 10% for Llama3-8B, and 92.8% to 18.8% for Gemma-7B, while baseline defenses still show high ASR. Refusal training, on the other hand, often fails to improve and sometimes even hurts model robustness, suggesting the necessity of adversarial training under malicious input perturbations. Finally, thanks to the regularization effect by the utility dataset, the impact of adversarial training on model general capability is overall negligible.

Efficiency of ReFAT against baseline defenses   We also found that, compared to existing adversarial training methods, ReFAT achieves similar or better robustness against various attacks. Notably, ReFAT achieves significantly lower ASR for the strongest type of RFA attack, while the other defenses are less effective against such continuous attacks that target residual stream activation. Moreover, ReFAT strengthens model safeguards at a much lower computational cost. In particular, R2D2, LAT and CAT require many more additional forward and backward passes than the normal fine-tuning runs, while ReFAT on average only needs 50% more model forward passes and no additional backward pass. As a result, ReFAT is on average 1,700x cheaper than R2D2 and 10x cheaper than CAT/LAT in terms of the total number forward and backward pass.

7 ANALYSES OF REFAT

Effects of ReFAT on model behavior   We examine how model behaviors under adversarial attacks change after ReFAT. Table 2 shows examples of Llama-3-8B-instruct answers to some AdvBench instructions when applying the strongest type of RFA attack. We observe that similar to discrete attacks such as GCG, RFA often jailbreaks the original Llama model by eliciting a starting sentence with compliant or friendly tones, and the model would then likely fall into a "helpful mode" and continue with generating a harmful response. In contrast, although the ReFAT-trained Llama is also steered to generate a verbally compliant start, it will remain semantically safe by either politely refusing the request or offering a detailed explanation of input harmfulness.

---

[6]We encountered memory and instability issues when training Gemma-7B with R2D2, and we leave this experiment for future work.

Like, you can't just use this vulnerability on any old server, you need Tomcat ... If you're using an older version, you're out of luck, bro |

Table 3: Sample GCG-modified AdvBench instructions that successfully jailbreak Llama-3-8B-Instruct with ReFAT. English translation of model answer (in Italian) for the first instruction is shown in parentheses.

Do RFA capture all adversarial vulnerabilities of LLMs? Table 3 presents several failed defenses of ReFAT where the adversarially trained Llama can still be jailbroken by GCG. We notice that these adversarial prompts often turn the model into a linguistic context that is very different from the harmless Alpaca instructions we used to compute the refusal features. In particular, the model remains less vigilant to input maliciousness when it is coerced to answer in languages other than English, or to talk colloquially in an under-represented English vernacular. Future work should address this limitation of the current ReFAT method by employing a semantically and linguistically more diverse set of instructions to compute refusal features.

8 CONCLUSION

Through interpretability analyses, we uncover a general jailbreaking mechanism used by adversarial attacks on LLMs, which involves ablating refusal features in the residual stream activation space. The refusal features can be approximated by the difference between the average hidden representations of harmful and harmless inputs. Additionally, we demonstrate that refusal feature ablation closely approximates the worst-case adversarial perturbations of compromising model safety, making it an effective method for simulating attacks during adversarial training. Leveraging these insights, we introduce ReFAT, a novel adversarial training algorithm that significantly improves the robustness of various LLMs against a broad range of attacks, while maintaining the models' general utility. Our study advances the understanding of LLM safety and adversarial vulnerabilities, demonstrating the potential of mechanistic interpretability in improving the transparency and reliability of generative AI systems.

9   ETHICS STATEMENT

This work introduces an efficient and interpretable adversarial training method aimed at enhancing the robustness of large language models (LLMs) against adversarial attacks. The positive impact of this research lies in its potential to reduce the amount of harmful content generated by LLMs, as it makes many types of attacks significantly less likely to succeed. Additionally, the lower computational cost of the proposed method could help decrease the carbon footprint associated with training robust and safe LLMs. However, there are potential risks. One concern is that increased robustness might lead to overconfidence in the safety of LLMs, highlighting the need for ongoing red teaming efforts. Another potential negative impact is the possibility that adversarial training could be misused to suppress content the model operator deems undesirable, regardless of its harmfulness. Finally, our analysis of ReFAT's failure modes reveals that LLMs may remain vulnerable to certain types of attacks (e.g., multilingual attacks), underscoring the importance of developing more rigorous and reliable evaluation protocols.

10   REPRODUCIBILITY STATEMENT

We describe in Section 5 the preparation of training and evaluation data for ReFAT, the implementation of ReFAT and baseline defenses, as well as the application of attack methods to evaluate LLM adversarial robustness. We also include additional experiment configurations and hyperparameters in Appendix A. We have thoroughly checked our data and code implementation, and we have also verified empirically the effectiveness of the proposed ReFAT method.

Table 4: Hyperparameters of ReFAT

APPENDIX A. ADDITIONAL EXPERIMENTAL DETAILS

Hyperparameters of ReFAT See Table 4 for a list of hyperparameters we used when fine-tuning LLMs via ReFAT, where $|\mathcal{D}_{\text{harmful}}|$ and $|\mathcal{D}_{\text{harmless}}|$ are the number of harmful and harmless instruction that we take to compute refusal features during training. We observed in preliminary experiments that training LLMs for 1 epoch would result in models with optimal levels of adversarial robustness, while fine-tuning more than 1 epoch would make models prone to overfitting and having higher average ASR. We also found that applying refusal feature ablation on the residual stream activations over the last 75% or the last 50% layers of each model often led to the most stable fine-tuning results. Finally, we found that choosing $p_{\text{RFA}} = 0.5$ (i.e., training models to refuse under RFA for 50% of the cases) best balances model safety on harmful instructions with and without adversarial modifications.

Experimental setups of baseline defenses We take the official implementations and default hyperparameters of R2D2 by (Mazeika et al., 2024) and CAT by (Xhonneux et al., 2024) respectively, and train both baselines on the same hybrid dataset of refusal and utility datasets as for ReFAT. Both R2D2 and CAT require minimizing the negative log likelihood of a safe answer (the "toward loss") and maximizing the negative log likelihood of a harmful answer (the "away loss"), and for the latter we take the completions provided by Zou et al. (2024) that are generated by an uncensored LLM conditioned on the 5000 harmful requests in their adversarial training dataset.

Further discussion on defense method hyperparameter choices We acknowledge that careful hyperparameter search is essential for each defense method to achieve optimal utility-robustness trade-off. However, due to the high computational cost of running expensive adversarial attacks such as GCG over the full evaluation dataset of 400 harmful instructions, we chose to determine best hyperparameter configurations by evaluating and comparing multiple variations of each defense method using a small set of 40 examples from AdvBench. We found that hyperparameters of CAT and R2D2 provided in their official implementations had been highly optimized, while slightly changing some of them (e.g. the relative weight of utility loss terms) often led to severe performance degradation, so we proceeded with their default hyperparameters. For ReFAT, we searched for best hyperparameters by experimenting with four different values of $p_{\text{RFA}} \in [0.25, 0.5, 0.75, 1.0]$ as well as four different sets of RFA layers (ablating all layers, ablating the last 75%, ablating the last 50%, and ablating the last 25%).

Although we have made our best attempt to optimize the performance of each defense method within a restricted computational budget, we acknowledge that a more careful hyperparameter search might lead to better utility-robustness trade-offs. However, we believe that our experimental results still offer strong empirical evidence that ReFAT could enhance model robustness and preserve general utility in a much more efficient way than traditional adversarial training methods.

Details of model robustness and utility evaluations We used the HarmBench implementations of GCG, PAIR, AutoDAN and HumanJailbreaks to attack all three LLMs. We adopted all default hyperparameters of the four attack methods, except for replacing the GPT-4 attacker model with the open-source Mixtral-8x7B-v0.1, and we observed no significant change in PAIR ASR compared to

Model	MMLU	MT-Bench
Llama-3-8B	65.9	7.24
+ RFA	65.5	7.07
Mistral-7B	58.9	7.02
+ RFA	58.1	6.97
Gemma-7B	52.0	6.60
+ RFA	51.8	6.74

Table 5: Model general capability before and after refusal feature clamping.

previous studies that used GPT-4 attacker models. For utility evaluation on MT-Bench, we also replaced GPT-4 with a non-proprietary Prometheus LLM judge model Kim et al. (2023), whose judge scores have high correlation with GPT-4-returned score rubrics across various NLP benchmarks including MT-Bench.

APPENDIX B. EFFECT OF REFUSAL FEATURE CLAMPING ON MODEL GENERATION QUALITY

To ensure that the decreased attack success rate shown in Section 3.3 after clamping RFs is not due to the degeneration of model generation capability, we further measured the average MMLU and MT-Bench scores for the three tested LLMs after undergoing RFA according to Equation 5. As shown in Table 5, we did not observe significant changes in model performance on either benchmarks, suggesting that refusal feature clamping does not affect model generation coherence, but instead only fixes model cautiousness to input safety at a relatively high level.

APPENDIX C. ADDITIONAL PCA VISUALIZATION OF RFA

Figure 6 - 17 illustrate the PCA-2D representations of AdvBench prompts and their adversarial modified counterparts by GCG/PAIR/AutoDAN/HumanJailbreaks respectively. Note that since the principal components are defined up to a sign, the relative visualized locations of prompt representations may get flipped across layers. As we can see, the separation between the original and adversarial harmful prompts emerges since early layers for all three LLMs. Moreover, hidden representations of adversarially modified prompts are consistently pushed closer to the cluster of safe Alpaca instructions as they progress through upper layers.

APPENDIX D. REFUSAL FEATURE HISTOGRAMS

Figure 18 and 19 show the distributions of residual stream activation values along the refusal directions (refusal features) across layers for two models: the `Meta-Llama-3-8B-Instruct` used in this study and the `gemma-2b-it` used in (Arditi et al., 2024). The figure 18 suggests that refusal features of harmless examples are not centered near zero for `Meta-Llama-3-8B-Instruct`. Hence, zeroing out along the refusal direction does not necessarily stop the model from refusing, and it may even cause the internal representations to fall out of distribution, potentially leading to degraded model performance.

In contrast, Figure 19 shows that for `gemma-2b-it` the refusal features of harmless examples are noticeably closer to zero. This observation may explain why Arditi et al. (2024) did not report performance degradation in their experiments.

APPENDIX E. ReFAT PSEUDO-CODE

We provide the pseudocode of ReFAT in Algorithm 1.

Algorithm 1 ReFAT

Require: $\theta, \mathcal{D}_r, \mathcal{D}_u, p_{\text{RFA}}, k$, optimizer
Ensure: θ_{ReFAT} ▷ Fine-tuned parameters
   $optimizer = \text{optimizer}(\theta)$ ▷ Initialize optimizer
   for $i = 0$ to max_steps **do**
       $(\mathbf{x}_r, \mathbf{y}_r), (\mathbf{x}_u, \mathbf{y}_u) \sim next\_batch(\mathcal{D}_r, \mathcal{D}_u)$ ▷ Extract harmful and utility samples
       if $i\%k = 0$ **then**
          $\mathbf{R_{HH}} = \{\mathbf{r}_{HH}^{(l)}\}_{l=1}^L$ ▷ Compute RFs: Eq. (2) with means over $\mathbf{x}_r, \mathbf{x}_u$
       end if
       if $\text{do}_{\text{RFA}} \sim \mathcal{B}(p_{\text{RFA}}) = 1$ **then**   ▷ Bernoulli draw
          $\mathbf{H}(\mathbf{x}_r) \leftarrow \mathbf{H}(\mathbf{x}_r) - \mathbf{R}_{\text{HH}}$ ▷ Remove RFs from harmful inputs' representations
       end if
       $\mathcal{L}_{\text{RFA,r}} = \text{mean}(f_\theta(\mathbf{y}_r|, \mathbf{x}_r, \mathbf{H}(\mathbf{x}_r)))$ ▷ Loss for harmful samples
       $\mathcal{L}_{\text{RFA,u}} = \text{mean}(f_\theta(\mathbf{y}_u|\mathbf{x}_u, \mathbf{H}(\mathbf{x}_u)))$ ▷ Loss for utility samples
       $\mathcal{L}_{\text{RFA}} = \mathcal{L}_{\text{RFA,r}} + \mathcal{L}_{\text{RFA,u}}$
       $\theta \leftarrow optimizer.step(\mathcal{L}_{\text{RFA}})$
   end for
   return $\theta_{\text{ReFAT}} \leftarrow \theta$

Table 6: Over-refusal assessment on MMLU questions.

APPENDIX F. ADDITIONAL EVALUATION OF OVER-REFUSALS

In Section 5, we provided an assessment of over-refusals by computing compliance rates on the challenging XSTest benchmark (Röttger et al., 2023), which includes harmless prompts that seem harmful. To complement this analysis, we follow Xhonneux et al. (2024) and compute the number of refusals on the 5,700 MMLU questions (Hendrycks et al., 2021) that should ideally not trigger any refusals. We report our results in Table 10. We find that the refusal rate on MMLU for ReFAT is at most 0.001, confirming that ReFAT does not induce significant over-refusals.
